

# Data Analysis Project: A Probabilistic Generative Grammar for Semantic Parsing

Abulhair Saparov

asaparov@cs.cmu.edu

Committee: Tom M. Mitchell, Taylor Berg-Kirkpatrick

## Abstract

We present a generative model of natural language sentences and demonstrate its application to semantic parsing. In the generative process, a logical form sampled from a prior, and conditioned on this logical form, a grammar probabilistically generates the output sentence. Grammar induction using MCMC is applied to learn the grammar given a set of labeled sentences with corresponding logical forms. We develop a semantic parser that finds the logical form with the highest posterior probability exactly. We obtain strong results on the GEOQUERY dataset and achieve state-of-the-art F1 on JOBS.

## 1 Introduction

Accurate and efficient semantic parsing is a long-standing goal in natural language processing. Existing approaches are quite successful in particular domains (Zettlemoyer and Collins, 2005, 2007; Wong and Mooney, 2007; Liang et al., 2011; Kwiatkowski et al., 2010, 2011, 2013; Li et al., 2013; Zhao and Huang, 2014; Dong and Lapata, 2016). However, they are largely domain-specific, relying on additional supervision such as a lexicon that provides the semantics or the type of each token in a set (Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010, 2011; Liang et al., 2011; Zhao and Huang, 2014; Dong and Lapata, 2016), or a set of initial synchronous context-free grammar rules (Wong and Mooney, 2007; Li et al., 2013). To apply the above systems to a new domain, additional supervision is necessary. When beginning to read text from a new domain, humans

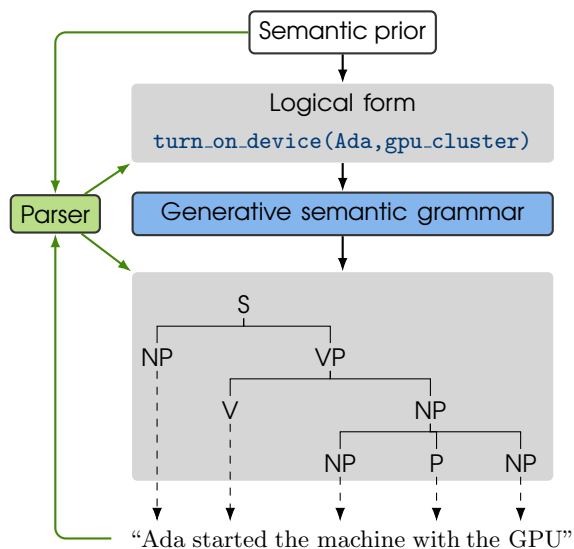

Figure 1: High-level illustration of the setting in which our grammar is applied in this paper. The dark arrows outline the generative process. During parsing, the input is the observed sentence, and we wish to find the most probable logical form and derivation given the training data under the semantic prior.

do not need to re-learn basic English grammar. Rather, they may encounter novel terminology. With this in mind, our approach is akin to that of (Kwiatkowski et al., 2013) where we provide domain-independent supervision to train a semantic parser on a new domain. More specifically, we restrict the rules that may be learned during training to a set that characterizes the general syntax of English. We hope our work provides a step toward the development of an open-domain semantic parser.

Knowledge plays a critical role in natural language understanding. Even seemingly trivial sentences may have a large number of ambiguous interpretations. Consider the sentence “Ada started the machine with the GPU,” for example. Without additional knowledge, such as the fact that “machine” can refer to computing devices that contain GPUs, or that

computers generally contain devices such as GPUs, the reader cannot determine whether the GPU is part of the machine or if the GPU is a device that is used to start machines. Context is highly instrumental to quickly and unambiguously understand sentences.

In contrast to most semantic parsers, which are built on discriminative models, our model is fully generative: To generate a sentence, the logical form is first drawn from a prior. A grammar then recursively constructs a derivation tree top-down, probabilistically selecting production rules from distributions that depend on the logical form (see Figure 1 for a high-level schematic diagram). The semantic prior distribution provides a straightforward way to incorporate background knowledge, such as information about the types of entities and predicates, or the context of the utterance. Additionally, our generative model presents a promising direction to *jointly* learn to understand and generate natural language.

This article describes the following contributions:

- In Section 2, we present our grammar formalism in its general form.
- Section 2.2 discusses aspects of the model in its application to the later experiments.
- In Section 3, we present a method to perform grammar induction in this model. Given a set of observed sentences and their corresponding logical forms, we apply Markov chain Monte Carlo (MCMC) to infer the posterior distributions of the production rules in the grammar.
- Given a trained grammar, we also develop a method to perform parsing in Section 4: to find the  $k$ -best logical forms for a given sentence, leveraging the semantic prior to guide its search.
- Using the GEOQUERY and JOBS datasets, we demonstrate in Section 7 that this framework can be applied to create natural language interfaces for semantic formalisms as complex as Datalog/lambda calculus, which contain variables, scope ambiguity, and superlatives.

All code is available at [github.com/asaparov](https://github.com/asaparov).

$$\begin{aligned}
 S &\rightarrow N:\text{select\_arg1} \quad VP:\text{delete\_arg1} \\
 VP &\rightarrow V:\text{identity} \quad N:\text{select\_arg2} \\
 VP &\rightarrow V:\text{identity} \\
 N &\rightarrow \text{“tennis”} & V &\rightarrow \text{“swims”} \\
 N &\rightarrow \text{“Andre Agassi”} & V &\rightarrow \text{“plays”} \\
 N &\rightarrow \text{“Chopin”}
 \end{aligned}$$

Figure 2: Example of a grammar in our framework. This grammar operates on logical forms of the form *predicate(first argument, second argument)*. The semantic function `select_arg1` returns the first argument of the logical form. Likewise, the function `select_arg2` returns the second argument. The function `delete_arg1` removes the first argument, and `identity` returns the logical form with no change.

Figure 3: Example of a derivation tree under the grammar given in Figure 2. The logical form corresponding to every node is shown in blue beside the respective node. The logical form for V is `plays_sport(,tennis)` and is omitted above to reduce clutter.

## 2 Semantic grammar

A grammar in our formalism operates over a set of nonterminals  $\mathcal{N}$  and a set of terminal symbols  $\mathcal{W}$ . It can be understood as an extension of a context-free grammar (CFG) (Chomsky, 1956) where the generative process for the syntax is dependent on a logical form, thereby coupling syntax with semantics. In the top-down generative process of a derivation tree, a logical form guides the selection of production rules. Production rules in our grammar have the form  $A \rightarrow B_1:f_1 \dots B_k:f_k$  where  $A \in \mathcal{N}$  is a nonterminal,  $B_i \in \mathcal{N} \cup \mathcal{W}$  are right-hand side symbols, and  $f_i$  are *semantic transformation functions*. These functions can encode how to “decompose” this logical form when recursively generating the subtrees rooted at each  $B_i$ . Thus, they enable semantic compositionality. An example of a grammar in this framework is shown in Figure 2, and a derivation tree is shown in Figure 3. Let  $\mathcal{R}$  be the set of production rules in the grammar and  $\mathcal{R}_A$  be the set of production rules with left-hand nonterminal symbol  $A$ .

## 2.1 Generative process

A *parse tree* (or *derivation*) in this formalism is a tree where every interior node is labeled with a nonterminal symbol, every leaf is labeled with a terminal, and the root node is labeled with the root nonterminal  $S$ . Moreover, every node in the tree is associated with a logical form: let  $x^n$  be the logical form assigned to the tree node  $\mathbf{n}$ , and  $x^{\mathbf{0}} = x$  for the root node  $\mathbf{0}$ .

The generative process to build a parse tree begins with the root nonterminal  $S$  and a logical form  $x$ . We *expand*  $S$  by randomly drawing a production rule from  $\mathcal{R}_S$ , *conditioned* on the logical form  $x$ . This provides the first level of child nodes in the derivation tree. So if, for example, the rule  $S \rightarrow B_1 : f_1 \dots B_k : f_k$  were drawn, the root node would have  $k$  child nodes,  $\mathbf{n}_1, \dots, \mathbf{n}_k$ , respectively labeled  $B_1, \dots, B_k$ . The logical forms associated with each node is determined by the semantic transformation function:  $x^{n_i} = f_i(x)$ . These functions describe the relationship between the logical form at a child node and that of its parent node. This process repeats recursively with every right-hand side nonterminal symbol, until there are no unexpanded nonterminal nodes. The sentence is obtained by taking the *yield* of the terminals in the tree (a concatenation).

## 2.2 Selecting production rules

In the above description, we did not specify the distribution from which rules are selected from  $\mathcal{R}_A$ . There are many design options available when specifying this distribution. In our approach, we choose a hierarchical Dirichlet process (HDP) prior (Teh et al., 2006). Every nonterminal in our grammar  $A \in \mathcal{N}$  will be associated with an HDP hierarchy. For each nonterminal, we specify a sequence of *semantic feature functions*,  $\{g_1, \dots, g_m\}$ , each of which return a discrete feature (such as an integer) of an input logical form  $x$ . We use this sequence of feature functions to define the hierarchy of the HDP: starting with the root node, we add a child node for every possible value of the first feature function  $g_1$ . For each of these child nodes, we add a grandchild node for every possible value of the second feature function  $g_2$ , and so forth. The result is a complete

tree of depth  $m$ . Each node  $\mathbf{n}$  in this tree is assigned a distribution  $G^n$  as follows:

$$\begin{aligned} G^{\mathbf{0}} &\sim \text{DP}(\alpha^{\mathbf{0}}, H), \\ G^n &\sim \text{DP}(\alpha^n, G^{\pi(\mathbf{n})}), \end{aligned} \quad (1)$$

where  $\mathbf{0}$  is the root node,  $\pi(\mathbf{n})$  is the parent of  $\mathbf{n}$ ,  $\alpha$  are a set of concentration parameters, and  $H$  is a base distribution over  $\mathcal{R}_A$ . This base distribution is independent of the logical form  $x$ .

In our implementation, we divide the set of nonterminals  $\mathcal{N}$  into two groups: (1) the set of “interior” nonterminals, and (2) preterminals. The production rules of preterminals are restricted such that the right-hand side contains only terminal symbols. The rules of interior nonterminals are restricted such that only nonterminal symbols appear on the right side.

1. For **preterminals**, we set  $H$  to be a distribution over sequences of terminal symbols as follows: we generate each token in the sequence i.i.d. from a uniform distribution over a finite set of terminals and a special *stop* symbol with probability  $\phi_A$ . Once the stop symbol is drawn, we have finished generating the rule. Note that we do not specify a set of domain-specific terminal symbols in defining this distribution.
2. For **interior nonterminals**, we specify  $H$  as a discrete distribution over a domain-independent set of production rules. Since these production rules contain semantic transformation functions, they are specific to the logical formalism.

We emphasize that only the prior is specified here, and we will infer the posterior to perform grammar induction. In principle, a more relaxed choice of  $H$  may enable grammar induction with new semantic formalisms and/or languages, if an efficient inference algorithm can be developed in such cases.

To select a rule in the generative process, given the logical form  $x$ , we can compute its feature values  $\{g_1(x), \dots, g_m(x)\}$  which specify a unique path in the HDP hierarchy to a leaf node  $G^x$ . We then draw the production rule from  $G^x$ . The specified set of production rules and semantic features are included with the code package. The specified rules and features are the same across all our experiments.

### 3 Induction

We describe grammar induction independently of the choice of rule distribution. Let  $\theta$  be the random variables in the grammar: in the case of the HDP prior,  $\theta$  is the set of all distributions  $G^n$  at every node in the hierarchies. Given a set of sentences  $\mathbf{y} \triangleq \{y_1, \dots, y_n\}$  and corresponding logical forms  $\mathbf{x} \triangleq \{x_1, \dots, x_n\}$ , we wish to compute the posterior  $p(\mathbf{t}, \theta | \mathbf{x}, \mathbf{y})$  over the grammar  $\theta$  and the latent derivations  $\mathbf{t} \triangleq \{t_1, \dots, t_n\}$ . This is intractable to compute exactly, and so we resort to Markov chain Monte Carlo (MCMC) (Gelfand and Smith, 1990; Robert and Casella, 2010). To perform blocked Gibbs sampling, we pick initial values for  $\mathbf{t}$  and  $\theta$  and repeat the following:

1. For  $i = 1, \dots, n$ , sample  $t_i | \theta, x_i, y_i$ .
2. Sample  $\theta | \mathbf{t}$ .

However, since the sampling of each tree  $t$  depends on  $\theta$ , and we need to resample all  $n$  parse trees before sampling  $\theta$ , this Markov chain can be slow to mix. Thus, we employ collapsed Gibbs sampling by integrating out  $\theta$ . In this algorithm, we repeatedly sample from  $t_i | \mathbf{t}_{-i}, x_i, y_i$  where  $\mathbf{t}_{-i} = \mathbf{t} \setminus \{t_i\}$ .

$$p(t_i | \mathbf{t}_{-i}, x_i, y_i) = \quad (2)$$

$$\mathbb{1}\{\text{yield}(t_i) = y_i\} \prod_{A \in \mathcal{N}} p\left( \bigcap_{\substack{\mathbf{n} \in t_i: \mathbf{n} \\ \text{has label } A}} r^{\mathbf{n}} \mid \mathbf{t}_{-i}, x_i \right),$$

where the intersection is taken over tree nodes  $\mathbf{n} \in t_i$  labeled with the nonterminal  $A$ ,  $r^{\mathbf{n}}$  is the production rule at node  $\mathbf{n}$ , and  $\mathbb{1}\{\cdot\}$  is 1 if the condition is true and zero otherwise. With  $\theta$  integrated out, the probability does not necessarily factorize over rules. In the case of the HDP prior, selecting a rule will increase the probability that the same rule is selected again (due to the ‘‘rich get richer’’ effect observed in the Chinese restaurant process). We instead use a Metropolis-Hastings step to sample  $t_i$ , where the proposal distribution is given by the fully factorized form:

$$p(t_i^* | \mathbf{t}_{-i}, x_i, y_i) = \quad (3)$$

$$\mathbb{1}\{\text{yield}(t_i^*) = y_i\} \prod_{\mathbf{n} \in t_i^*} p(r^{\mathbf{n}} \mid \mathbf{t}_{-i}, x_i^{\mathbf{n}}).$$

After sampling  $t_i^*$ , we choose to accept the new sample with probability

$$\frac{\prod_{\mathbf{n} \in t_i} p(r^{\mathbf{n}} | x^{\mathbf{n}}, \mathbf{t}_{-i}) p\left(\bigcap_{\mathbf{n} \in t_i^*} r^{\mathbf{n}} | x, \mathbf{t}_{-i}\right)}{p\left(\bigcap_{\mathbf{n} \in t_i} r^{\mathbf{n}} | x, \mathbf{t}_{-i}\right) \prod_{\mathbf{n} \in t_i^*} p(r^{\mathbf{n}} | x^{\mathbf{n}}, \mathbf{t}_{-i})},$$

where  $t_i$ , here, is the old sample, and  $t_i^*$  is the newly proposed sample. In practice, this acceptance probability is very high. This approach is very similar in structure to that in Johnson et al. (2007); Blunsom and Cohn (2010); Cohn et al. (2010).

If an application requires posterior samples of the grammar variables  $\theta$ , we can obtain them by drawing from  $\theta | \mathbf{t}$  after the collapsed Gibbs sampler has mixed.

Refer to Saparov and Mitchell (2016) for details on HDP inference and computing  $p(r^{\mathbf{n}} | x^{\mathbf{n}}, \mathbf{t}_{-i})$ .

#### 3.1 Sampling $t_i^*$

To sample from equation (3), we use inside-outside sampling (Finkel et al., 2006; Johnson et al., 2007), a dynamic programming approach, where the inside step is implemented using an agenda-driven chart parser (Indurkha and Damerau, 2010). The algorithm fills a chart, which has a cell for every nonterminal  $A$ , sentence start position  $i$ , end position  $j$ , and logical form  $x$ . The algorithm aims to compute the *inside probability* of every chart cell: that is, for every cell  $(A, i, j, x)$ , we compute the probability that  $t_i^*$  contains a subtree rooted with the nonterminal  $A$  and logical form  $x$ , spanning the sentence positions  $(i, j)$ . Let  $I_{(A, i, j, x)}$  be the inside probability at the chart cell  $(A, i, j, x)$ :

$$I_{(A, i, j, x)} = \sum_{A \rightarrow B_1: f_1 \dots B_K: f_K} \sum_{i=l_1 < \dots < l_{K+1}=j} \prod_{u=1}^K I_{(B_u, l_u, l_{u+1}, f_u(x))}. \quad (4)$$

Each item in the agenda represents a snapshot of the computation of this expression for a single rule  $A \rightarrow B_1: f_1 \dots B_K: f_K$ . The agenda item stores the current position in the rule  $k$ , the set of sentence spans that correspond to the first  $k$  right-hand side symbols  $l_1, \dots, l_{k+1}$ , the span of the rule  $(i, j)$ , the logical form  $x$ , and the inside probability of the portion of the

rule computed so far. At every iteration, the algorithm pops an item from the agenda and adds it to the chart, and considers the next right-hand side symbol  $B_k$ .

- If  $B_k$  is a terminal, it will match it against the input sentence. If the terminal does not match the sentence, this agenda item is discarded and the algorithm continues to the next iteration. If the terminal does match, the algorithm *increments* the rule. That is, for each possible value of  $l_{k+2}$ , the algorithm constructs a new agenda item containing the same contents as the old agenda item, but with rule position  $k + 1$ .
- If  $B_k$  is a nonterminal, the algorithm will *expand* it (if it was not previously expanded at this cell). The algorithm considers every production rule of the form  $B_k \rightarrow \beta$ , and every possible end position for the next nonterminal  $l_{k+2} = l_{k+1} + 1, \dots, j - 1$ , and enqueues a new agenda item with rule  $B_k \rightarrow \beta$ , rule position set to 1, span set to  $(l_k, l_{k+1})$ , logical form set to  $f_k(x)$ , and inside probability initialized to 1. The original agenda item is said to be “waiting” for  $B_k$  to be completed later on in the algorithm.
- If the rule is *complete* (there are no subsequent symbols in the rule of this agenda item), we can compute its inner probability  $p(A \rightarrow B_1 : f_1 \dots B_K : f_K | x, \mathbf{t}_{-i})$ . First, we record that this rule was used to complete the left-hand nonterminal  $A$  at the cell  $(A, i, j, x)$ . Then, we consider every agenda item in the chart that is currently “waiting” for the left-hand nonterminal  $A$  at this sentence span. The search *increments* each “waiting” item, adding a new item to the agenda for each, whose log probability is the sum of the log probability of the old agenda item and the log probability of the completed rule.

We prioritize items in the agenda by  $i - j$  (so items with smaller spans are dequeued first). This ensures that whenever the search considers expanding  $B_k$ , if  $B_k$  was previously expanded at this cell, its inside probability is fully computed. Thus, we can avoid re-expanding  $B_k$  and directly increment the agenda item. The algorithm terminates when there are no items in the agenda.

All that remains is the outside step: to sample the tree given the computed inside probabilities. To do so, we begin with the chart cell  $(S, 0, |y_i|, x_i)$  where  $|y_i|$  is the length of sentence  $y_i$ , and we consider all completed rules at this cell (these rules will be of the form  $S \rightarrow \beta$ ). Each rule will have a computed inside probability, and we can sample the rule from the categorical distribution according to these inside probabilities. Then, we consider the right-hand side nonterminals in the selected rule, and continue sampling recursively. The end result is a tree sampled from equation (3).

## 4 Parsing

For a new sentence  $y_*$ , we aim to find the logical form  $x_*$  and derivation  $t_*$  that maximizes

$$\begin{aligned} p(x_*, t_* | y_*, \boldsymbol{\theta}) &\propto p(x_*)p(y_* | t_*)p(t_* | x_*, \boldsymbol{\theta}), \\ &= \mathbb{1}\{\text{yield}(t_*) = y_*\}p(x_*) \prod_{n \in t_*} p(r^n | x_*^n, \boldsymbol{\theta}). \end{aligned} \quad (5)$$

We first describe an algorithm to compute the derivation  $t_*$  that maximizes the above quantity, given the logical form  $x_*$  and input sentence  $y_*$ . We will later demonstrate how this algorithm can be used to find the optimal logical form and derivation  $x_*, t_*$ . To find the optimal  $t_*$ , we again use an agenda-driven chart parser to perform the optimization, with a number of important differences. Each agenda item will keep track of the derivation tree completed so far.

The algorithm is very similar in structure to the inside algorithm described above. At every iteration of the algorithm, an item is popped from the agenda and added to the chart, applying one of the three operations available to the inside algorithm. The algorithm begins by expanding the root nonterminal  $S$  at  $(0, |y_*|)$  with the logical form  $x_*$ .

### 4.1 Agenda prioritization

The most important difference from the inside algorithm is the prioritization of agenda items. For a given agenda item with rule  $A \rightarrow B_1 : f_1 \dots B_K : f_K$  with logical form  $x$  at sentence position  $(i, j)$ , we aim to assign as its priority an upper bound on equation (5) for any derivation that contains this rule at this position. To do so, we can split the product in the objective  $\prod_{n \in t_*} p(r^n | x_*^n, \boldsymbol{\theta})$  into a product

Figure 4: Decomposition of a parse tree into its left outer parse, inner parse, and its right outer parse. This is one example of such a decomposition. For instance, we may similarly produce a decomposition where the prepositional phrase is the inner parse, or where the verb is the inner parse. The terminals are omitted and only the syntactic portion of the parse is displayed here for conciseness.

of two components: (1) the *inner probability* is the product of the terms that correspond to the subtree of  $t_*$  rooted at the current agenda item, and (2) the *outer probability* is the product of the remaining terms, which correspond to the parts of  $t_*$  outside of the subtree rooted at the agenda item. A schematic decomposition of a derivation tree is shown in Figure 4.

We define an upper bound on the log inner probability  $I_{(A,i,j)}$  for any subtree rooted at nonterminal  $A$  at sentence span  $(i, j)$ .

$$I_{(A,i,j)} \triangleq \max_{A \rightarrow B_1 \dots B_K} \left( \max_{x'} \log p(A \rightarrow B_1, \dots, B_K | x', \theta) + \max_{l_2 < \dots < l_K} \sum_{k=1}^K I_{(B_k, l_k, l_{k+1})} \right), \quad (6)$$

where  $l_1 = i$ ,  $l_{K+1} = j$ . Note that the left term is a maximum over all logical forms  $x'$ , and so this upper bound only considers syntactic information. The right term can be maximized using dynamic programming in  $\mathcal{O}(K^2)$ . As such, classical syntactic parsing algorithms can be applied to compute  $I$  for every chart cell in  $\mathcal{O}(n^3)$ . For any terminal symbol  $T$ , we define  $I_{(T,i,j)} = 0$ .

We similarly define  $O_{(A,i,j,x)}$  representing a bound on the outer probability at every cell.

$$O_{(A,i,j,x)} \triangleq \max_{\{t: \text{yield}(t) = y_*\}} \left( \log p(x) + \log p(t_L | x, \theta) + \sum_{(A', i', j') \in r(t_R)} I_{(A', i', j')} \right), \quad (7)$$

where the maximum is taken over  $t$  which is a derivation containing a subtree rooted at  $A$  at sentence position  $(i, j)$ . In this expression,  $t_L$  is the outer-left portion of the derivation tree  $t$ ,  $t_R$  is the outer-right portion, and  $r(t_R)$  is the set of root vertices of the trees in  $t_R$ .

Using these two upper bounds, we define the priority of any agenda item with rule  $A \rightarrow B_1 : f_1 \dots B_K : f_K$  at rule position  $k$ , with log probability score  $\rho$ , and logical form  $x$  as:

$$\rho + \max_{l_{k+2} < \dots < l_{K+1}} \sum_{u=k}^K I_{(B_u, l_u, l_{u+1})} + O_{(A, i, j, x)}. \quad (8)$$

**Thm 1.** *If the priority of agenda items is computed as in equation (8), then at every iteration of the chart parser, the priority of new agenda items will be at most the priority of the current item.*

*Proof.* See supplementary material A.

Thus, the search is *monotonic*<sup>1</sup>. That is, the maximum priority of items in the agenda never increases.

This property allows us to compute the outer probability bound  $O_{(A, i, j, x)}$  for free. Computing it directly is intractable. Consider the expansion step for an agenda item with rule  $A \rightarrow B_1 : f_1 \dots B_K : f_K$  at rule position  $k$ , with log probability score  $\rho$ , and logical form  $x$ . The nonterminal  $B_k$  is expanded next at sentence position  $(l_k, l_{k+1})$ , and its outer probability is simply

$$O_{(B_k, l_k, l_{k+1}, f_k(x))} = \rho + \max_{l_{k+2} < \dots < l_{K+1}} \sum_{u=k+1}^K I_{(B_u, l_u, l_{u+1})} + O_{(A, i, j, x)}. \quad (9)$$

The monotonicity of the search guarantees that any subsequent expansion of  $B_k$  at  $(l_k, l_{k+1})$  will not yield a more optimal bound.

Monotonicity also guarantees that when the algorithm completes a derivation for the root nonterminal  $S$ , it is optimal (i.e. the Viterbi parse). In this way, we can continue execution to obtain the  $k$ -best parses for the given sentence.

<sup>1</sup>In the formulation of the algorithm as an A\* search, the heuristic is *consistent*.

## 4.2 Optimization over logical forms

The above algorithm finds the optimal derivation  $t_*$ , given a sentence  $y_*$  and logical form  $x_*$ . To jointly optimize over both the derivation and logical form, imagine beginning the algorithm by repeatedly expanding the root nonterminal for *every* logical form. This would create of a new agenda item for every logical form, which is identical in every field except for the logical form (and therefore, its prior probability). Thus, we can represent this set of agenda items as a single agenda item, where instead of an individual logical form  $x$ , we store a logical form set  $X$ . The outer probability bound is now defined over sets of logical forms:  $O_{(A,i,j,X)} \triangleq \max_{x \in X} O_{(A,i,j,x)}$ . We can use this quantity in equation (8) to compute the priority of these ‘‘aggregated’’ agenda items. Thus, this algorithm is a kind of branch-and-bound approach to the combinatorial optimization problem. A sparse representation of a set of logical forms is essential for efficient parsing.

Another difference arises after completing the parsing of a rule  $A \rightarrow B_1 : f_1 \dots B_K : f_K$  with a set of logical forms  $X$ , where we need to compute  $\log p(A \rightarrow B_1 : f_1 \dots B_K : f_K | x, \theta^{(t)})$ . In the inside algorithm, this was straightforward since there was only a single logical form. But in the parsing setting,  $X$  is a set of logical forms, and the aforementioned probability can vary across instances within this set (for the HDP prior, for example, the set may correspond to multiple distinct paths in the HDP hierarchy). Therefore, we divide  $X$  into its equivalence classes. More precisely, consider the set of disjoint subsets of  $X = X_1 \cup \dots \cup X_m$  where  $X_i \cap X_j = \emptyset$  for  $i \neq j$ , such that  $p(A \rightarrow B_1 : f_1 \dots B_K : f_K | x', \theta^{(t)})$  is the same for every  $x' \in X_i$ . For each equivalence class  $X_i$ , we create a ‘‘completed nonterminal’’ item with the appropriate parse tree, log probability, and logical form set  $X_i$ . With these, we continue inspecting the chart for search states ‘‘waiting’’ for the nonterminal  $A$ .

The *increment* operation is also slightly different in the parser. When we increment a rule  $A \rightarrow B_1 : f_1 \dots B_K : f_K$  after completing parsing for the symbol  $B_k$  with logical form set  $X$ , we create a new agenda item with the same contents as the old item, but with the rule po-

sition increased by one. The log probability of the new agenda item is the sum of the log probabilities of the old agenda item and the completed subtree. Similarly the logical form set of the new agenda item will be the intersection of  $\{f_k^{-1}(x) : x \in X\}$  and the logical forms in the old agenda item.

Our implementation is available for reference at [github.com/asaparov](https://github.com/asaparov).

## 5 Generation

To generate a sentence for a given logical form  $x_*$ , there are two approaches: (1) sample from  $y_*, t_* | x_*, \mathbf{x}, \mathbf{y}$  where  $\mathbf{x}, \mathbf{y}$  are the training sentences and logical forms, respectively, or (2) find the sentence  $y_*$  and derivation  $t_*$  that maximize  $p(y_*, t_* | x_*, \theta)$  for the grammar  $\theta$ . We can re-write the probability of the new derivation:

$$\begin{aligned} p(y_*, t_* | x_*, \mathbf{x}, \mathbf{y}) & \quad (10) \\ &= p(y_* | t_*) \int p(t_* | x_*, \theta) dp(\theta | \mathbf{x}, \mathbf{y}), \\ &\approx \frac{\mathbb{1}\{\text{yield}(t_*) = y_*\}}{N} \sum_{\theta^{(t)} \sim \theta | \mathbf{x}, \mathbf{y}} p(t_* | x_*, \theta^{(t)}), \\ &= \frac{\mathbb{1}\{\text{yield}(t_*) = y_*\}}{N} \sum_{\theta^{(t)} \sim \theta | \mathbf{x}, \mathbf{y}} \prod_{n \in t_*} p(r^n | x_*^n, \theta^{(t)}), \end{aligned}$$

Sampling from this distribution is straightforward, due to the generative nature of the model. The above expression is the probability of a mixture model, and so with probability  $1/N$ , we randomly select the sample  $\theta^{(t)}$ . Next, we start constructing the derivation tree at the root nonterminal  $S$  and select a production rule of the form  $S \rightarrow \beta$  according to  $p(S \rightarrow \beta | x_*, \theta^{(t)})$ . Then we repeat this process recursively with each right-hand side nonterminal in the selected production rule. At the end of this process, we will have produced a derivation  $t_*$  and sentence  $y_* = \text{yield}(t_*)$ .

The second approach for generation is to find the derivation  $t_*$  and sentence  $y_*$  that maximizes

$$\begin{aligned} p(y_*, t_* | x_*, \theta) & \\ &= \mathbb{1}\{\text{yield}(t_*) = y_*\} \prod_{n \in t_*} p(r^n | x_*^n, \theta). \quad (11) \end{aligned}$$

We can augment the parser to perform this optimization. The major difference is that ex-

Method	GEOQUERY			JOBS

Figure 5: The methods in the top part of the table were evaluated using 10-fold cross validation, whereas those in the bottom part were evaluated with an independent test set. \*WASP and  $\lambda$ -WASP were trained on 792 examples

Logical form:	<code>answer(A, smallest(A, state(A)))</code>	<code>answer(A, largest(B, (state(A), population(A, B))))</code>
Test sentence:	“Which state is the smallest?”	“Which state has the most population?”
Generated:	“What state is the smallest?”	“What is the state with the largest population?”

Figure 6: Examples of sentences generated from our trained grammar on logical forms in the GEOQUERY test set. Generation is performed by computing  $\arg \max_{y_*} p(y_* | x_*, \theta)$ .

panding a terminal symbol will always increment the agenda item (whereas in the parser, the terminal must match the appropriate token in the sentence). We use the same agenda prioritization as described in section 4.1, except that we use a trivial upper bound on the inner probabilities  $I = 0$  at every cell, since there is no input sentence. Monotonicity is still guaranteed, and so when the search first completes  $k$  derivations, they are optimal.

## 6 Semantic prior

The modular nature of the semantic prior allows us to explore many different models of logical forms. We experiment with a fairly straightforward prior: Predicate instances are generated left-to-right, conditioned only on the last predicate instance that was sampled for each variable. When a predicate instance is sampled, its predicate, arity, and “direction”<sup>2</sup> are simultaneously sampled from a categorical distribution. Functions like `largest`, `shortest`, etc, are sampled in the same process. We again use an HDP to model the discrete distribution conditioned on a discrete random variable.

We also follow Wong and Mooney (2007); Li et al. (2013); Zhao and Huang (2014) and

<sup>2</sup>`size(A)`, `size(A, B)`, vs `size(B, A)`, etc.

experiment with a type-correctness constraint, where the logical form is distributed according to the aforementioned prior, conditioned on the fact that the logical form is type-correct. Type-incorrect logical forms have zero prior probability.

## 7 Results

To evaluate our parser, we use the GEOQUERY and JOBS datasets. Following Zettlemoyer and Collins (2007), we use the same 600 GEOQUERY sentences for training and an independent test set of 280 sentences. On JOBS, we use the same 500 sentences for training and 140 for testing. We run our parser with two setups: (1) with no domain-specific supervision, and (2) using a small domain-specific lexicon and a set of beliefs (such as the fact that Portland is a city). A given output logical form is considered correct if it is semantically equivalent to the true logical form.<sup>3</sup> We measure the precision and recall of our method, where precision is the number of correct parses divided by the number of sentences for which our parser provided output, and recall is the number of correct parses divided by the total number of sentences in each dataset. Our results are shown

<sup>3</sup>The result of execution of the output logical form is identical to that of the true logical form, for any grounding knowledge base/possible world.

compared against many other semantic parsers in Figure 5. Our method is labeled SG for “semantic grammar.” In our experiments, we found that the sampler converges rapidly, requiring only 10 passes over the data. This is due to our restriction of the interior production rules to a domain-independent set.

Many sentences in the test set contain tokens previously unseen in the training set. In such cases, the maximum possible recall is 88.2 and 82.3 on GEOQUERY and JOBS, respectively. Therefore, we also measure the effect of adding a domain-specific lexicon, which maps semantic constants like `maine` to the noun “maine” for example. This lexicon is analogous to the string-matching and argument identification steps in the competing parsers.

As expected, the addition of a lexicon and type-checking greatly improves parsing performance. However, even without domain-specific supervision, the parser performs reasonably well. Our method achieves state-of-the-art F1 on the JOBS dataset. However, we notice a common error is the incorrect determination of scope of functions like `highest`, `shortest`, etc. This is likely due to the fact that the semantic prior does not explicitly model the scope of these functions (it places a uniform probability on all possible scopes). Thus, a more explicit model of scope might further improve parsing performance.

## 8 Related work

Our grammar formalism can be related to synchronous CFGs (SCFGs) (Aho and Ullman, 1972) where the semantics and syntax are generated simultaneously. However, instead of modeling the joint probability of the logical form and natural language utterance  $p(x, y)$ , we model the factorized probability  $p(x)p(y|x)$ . Modeling each component in isolation provides a cleaner division between syntax and semantics, and one half of the model can be modified without affecting the other (such as the addition of new background knowledge, or changing the language/logical formalism). We used a CFG in the syntactic portion of our model (although our grammar is not context-free, due to the dependence on the logical form). Richer syntactic formalisms such as combi-

natory categorial grammar (Steedman, 1996) or head-driven phrase structure grammar (Pollard and Sag, 1994) could replace the syntactic component in our framework and may provide a more uniform analysis across languages. Our model is similar to lexical functional grammar (LFG) (Kaplan and Bresnan, 1995), where  $f$ -structures are replaced with logical forms. Nothing in our model precludes incorporating syntactic information like  $f$ -structures into the logical form, and as such, LFG is realized in our framework. Our approach can be used to define new generative models of these grammatical formalisms. We implemented our method with a particular semantic formalism, but the grammatical model is agnostic to the choice of semantic formalism or the language. As in some previous parsers, a parallel can be drawn between our parsing problem and the problem of finding shortest paths in hypergraphs using A\* search (Klein and Manning, 2001, 2003; Pauls and Klein, 2009; Pauls et al., 2010; Gallo et al., 1993).

## 9 Discussion

In this article, we presented a generative model of sentences, where each sentence is generated recursively top-down according to a semantic grammar, where each step is conditioned on the logical form. We developed a method to learn the posterior of the grammar using a Metropolis-Hastings sampler. We also derived a Viterbi parsing algorithm that takes into account the prior probability of the logical forms. Through this semantic prior, background knowledge and other information can be easily incorporated to better guide the parser during its search. Our parser provides state-of-the-art results when compared with competing approaches.

As a generative model, there are promising applications to interactive learning, caption generation, data augmentation, etc. Although we provided qualitative results for sentence generation, we would like to perform a more thorough quantitative evaluation. Richer semantic priors can be applied to perform ontology learning, relation extraction, or context modeling. Applying this work to semi-supervised settings is also interesting. The avenues for future work are numerous.

## A Proof of Thm 1

Induct on the iteration of the algorithm. Let  $a$  be the current agenda item, where the production rule of the item is  $A \rightarrow B_1:f_1 \dots B_K:f_K$ , the rule position is  $k$ , the set of sentence spans that correspond to the first  $k$  right-hand side symbols is  $l_1, \dots, l_{k+1}$ , the span of the rule is  $(i, j)$ , the logical form is  $x$ , and the log probability of the first  $k$  right-hand side symbols is  $\rho$ . For notational brevity, we let  $c(a)$  denote the priority of the agenda item  $a$  as defined in equation (8). There are three cases:

**Case 1** If  $B_k$  is a terminal, a new agenda item is created only if the terminal matches the token in the input sentence. Then for each possible value of  $l_{k+2}$ , a new agenda item  $a'$  is created, where  $\rho$  is the same as that in the old agenda item  $a$ . Since the logical form is the same, and

$$\begin{aligned} I_{(B_k, l_k, l_{k+1})} + \max_{l_{k+3} < \dots < l_{K+1}} \sum_{u=k+1}^K I_{(B_u, l_u, l_{u+1})} \\ \leq \max_{l_{k+2} < \dots < l_{K+1}} \sum_{u=k}^K I_{(B_u, l_u, l_{u+1})}, \end{aligned}$$

the priority of the new agenda item is at most that of the old item  $c(a') \leq c(a)$ .

**Case 2** If  $B_k$  is a nonterminal, it proceeds to “expand” it. Suppose to the contrary that we create an agenda item whose priority is greater than that of the current item. This implies that there exists a production rule

$B_k \rightarrow C_1 \dots C_{K'}$  and a set of sentence spans  $l'_2 < \dots < l'_{K'+1}$  such that

$$\begin{aligned} c(a) = & \rho + \max_{l_{k+2} < \dots < l_{K+1}} \sum_{u=k}^K I_{(B_u, l_u, l_{u+1})} + O_{(A, i, j, x)}, \\ & < \sum_{u=1}^{K'} I_{(C_u, l'_u, l'_{u+1})} + O_{(B_k, l_k, l_{k+1}, f_k(x))} \\ & \leq I_{(B_k, l_k, l_{k+1})} + O_{(B_k, l_k, l_{k+1}, f_k(x))}, \end{aligned}$$

where  $l'_1 = l_k$  and  $l'_{K'+1} = l_{k+1}$ . By definition of the bound on the outer probability, the above inequality implies that there exists a derivation  $t'$  and logical form  $x'$  such that  $f_k(x') = f_k(x)$  and

$$\begin{aligned} c(a) < \log p(x') + \log p(t'_L | x', \theta) \\ + I_{(B_k, l_k, l_{k+1})} + \sum_{(A', i', j') \in r(t'_R)} I_{(A', i', j')}. \end{aligned} \quad (12)$$

Let  $D \rightarrow E_1 \dots E_{K''}$  be the production rule in  $t'$  that contains the  $B_k$  nonterminal at sentence span  $(l_k, l_{k+1})$ , and so for some  $m$ ,  $E_m = B_k$ . In addition, let  $s'_i$  be the sibling derivation tree rooted at  $E_i$  for all  $i = 1, \dots, m-1$ . Therefore, there must exist an agenda item  $a'$  with the same production rule, with rule position  $m$ ,  $(l_k, l_{k+1})$  as the sentence spans of  $D_m$ , log probability of the first  $m$  right-hand side symbols  $\sum_{i=1}^{m-1} \log p(s'_i | x', \theta^{(t)})$ , and logical form  $x'$ . The priority of this rule state is

$$\begin{aligned} c(a') = \sum_{i=1}^{m-1} \log p(s'_i | x', \theta) \\ + \max_{l_{m+2} < \dots < l_{K''+1}} \sum_{u=m}^{K''} I_{(E_u, l_u, l_{u+1})} + O_{(D, i', j', x')}. \end{aligned}$$

By definition of the outer probability bound, we have  $O_{(D, i', j', x')} \geq \log p(x') + \log p(t''_L | x', \theta) + \sum_{(A', i', j') \in r(t''_R)} I_{(A', i', j')}$  where  $t''_L$  is the outer-left portion of the derivation tree  $t'$  not containing the subtree rooted at the nonterminal  $C$ , and  $t''_R$  is similarly the outer-right portion. Thus, we can lower

bound  $c(a')$

$$c(a') \geq$$

$$\log p(x') + \log p(t'_L|x', \theta) + \sum_{i=1}^{m-1} \log p(s'_i|x', \theta) \\ + \max_{l_{m+2} < \dots < l_{K''+1}} \sum_{u=m}^{K''} I_{(D_u, l_u, l_{u+1})} + \sum_{(A', i', j') \in r(t'_R)} I_{(A', i', j')},$$

which is at least the quantity in equation (12), since

$$\log p(t'_L|x', \theta) = \\ \log p(t''_L|x', \theta) + \sum_{i=1}^{m-1} \log p(s'_i|x', \theta), \\ \sum_{(A', i', j') \in r(t'_R)} I_{(A', i', j')} \leq \\ \max_{l_{m+2} < \dots < l_{K''+1}} \sum_{u=m+1}^{K''} I_{(D_u, l_u, l_{u+1})} + \sum_{(A', i', j') \in r(t'_R)} I_{(A', i', j')}.$$

Thus,  $c(a') > c(a)$ , and so by the inductive hypothesis,  $a'$  was processed by the algorithm at an earlier iteration. However, this would mean that the nonterminal  $B_k$  is expanded more than once at the sentence location  $(l_k, l_{k+1})$ , which is disallowed.

**Case 3** If the rule is complete, the algorithm looks for previously-processed agenda items that are “waiting” for a derivation of  $B_k$  at positions  $(l_k, l_{k+1})$ . The algorithm will combine the completed derivation with the waiting state and create a new agenda item where the rule position is incremented by 1. Suppose to the contrary that the new agenda item  $a'$  has priority greater than the current item  $a$ . Let the production rule of  $a'$  be  $D \rightarrow E_1 : f_1 \dots E_{K'} : f_{K'}$  where  $E_m = A$  for some  $m$ , and so  $m$  is the rule position of  $a'$ . Additionally, let the sentence spans of the first  $m-1$  right-hand symbols be  $l'_1, \dots, l'_{m-1}$ , and  $\rho'$  is the log probability of the first  $m-1$  right-hand symbols, and the logical form is  $x'$  where  $f_m(x') = x$ . Therefore, we can write

$$c(a) = \log p(t'_A|x, \theta) + O_{(A, i, j, x)}, \\ < \rho' + \log p(t'_A|x, \theta) + O_{(D, i', j', x')} \\ + \max_{l_{m+3} < \dots < l_{K'}} \sum_{u=m+1}^{K'} I_{(D_u, l_u, l'_{u+1})} = c(a').$$

This expression implies

$$O_{(A, i, j, x)} < \rho' + \\ \max_{l_{m+3} < \dots < l_{K'}} \sum_{u=m+1}^{K'} I_{(D_u, l_u, l'_{u+1})} + O_{(C, i', j', x')},$$

but this is not possible by the definition of  $O_{(A, i, j, x)}$  in equation (7), as we would have found a derivation with a strictly better objective. ■
